lgcp – An R Package for Inference with Spatial and Spatio-Temporal Log-Gaussian Cox Processes

Benjamin M. Taylor Lancaster University, UK Tilman M. Davies University of Otago, NZ

Barry S. Rowlingson Lancaster University, UK Peter J. Diggle Lancaster University, UK

Abstract

This paper introduces an R package for spatial and spatio-temporal prediction and forecasting for log-Gaussian Cox processes. The main computational tool for these models is Markov chain Monte Carlo and the new package, **lgcp**, therefore also provides an extensible suite of functions for implementing MCMC algorithms for processes of this type. The modelling framework and details of inferential procedures are first presented before a tour of **lgcp** functionality is given via a walk-through data-analysis. Topics covered include reading in and converting data, estimation of the key components and parameters of the model, specifying output and simulation quantities, computation of Monte Carlo expectations, post-processing and simulation of data sets.

Keywords: Cox process; R; spatio-temporal point process.

Contents

1. Introduction

This article introduces a new R (R Development Core Team 2011) package, $\lg cp$, for inference with spatial and spatio-temporal log-Gaussian Cox processes. The work was motivated by applications in disease surveillance, where the major focus of scientific interest is on whether, and if so where and when, cases form unexplained clusters within a spatial region W and time-interval (0,T) of interest. It will be assumed that both the location and time of each case is known, at least to a sufficiently fine resolution that a point process modelling framework is natural. In general, the aims of statistical analysis include model formulation, parameter estimation and spatio-temporal prediction. The $\lg cp$ package includes some functionality for parameter estimation and diagnostic checking, mostly by linkages with other R packages for spatial statistics. However, and consistent with the scientific focus being on disease surveillance, the current version of the package places particular emphasis on real-time predictive inference. Specifically, using the modelling framework of a Cox process with stochastic intensity $R(s,t) = \lambda(s)\mu(t) \exp{\{\mathcal{Y}(s,t)\}}$, where $\mathcal{Y}(s,t)$ is a Gaussian process and λ and μ are offset terms supplied by the user. The package enables the user to draw samples from the

joint predictive distribution of $R(s, [t_1, t_2])$ for some time interval $[t_1, t_2]$ as well as forecast beyond the last observation at time T, i.e., R(s, T + k) given data between times T - l and T, where l is a user-specified lag time for any set of locations $s \in W$ and forecast lead time $k \geq 0$. In the surveillance setting, these samples would typically be used to evaluate the predictive probability that the intensity at a particular location and time exceeds a specified intervention threshold; see, for example, Diggle, Rowlingson, and Su (2005).

The **lgcp** package makes extensive use of **spatstat** functions and data structures (Baddeley and Turner 2005). Other important dependencies are: the **sp** package, which also supplies some data structures and functions (Pebesma and Bivand 2005; Bivand, Pebesma, and Gomez-Rubio 2008); the suite of covariance functions provided by the **RandomFields** package (Schlather 2001); the **rpanel** package to facilitate minimum-contrast parameter estimation routines (Bowman, Crawford, Alexander, and Bowman 2007; Bowman, Gibson, Scott, and Crawford 2010); and the **ncdf** package for rapid access to massive datasets for post-processing (Pierce 2011).

In Section 2 the log-Gaussian Cox process is introduced. Section 3 gives a review on methods of inference for log-Gaussian Cox processes. Section 4 is an overview of the package by way of a walk-through example, covering: reading in data (Section 4.2); estimating components of the model and associated parameters (Sections 4.3 and 4.4); setting up and running the model (Sections 4.5 and 4.6); and post-processing of command outputs (Section 4.7). Some possible extensions of the package are given in Section 5. The appendices give further information on the rotation of observation windows (Appendix A), simulation of data (Appendix B) and information about the spatialAtRisk class of objects (Appendix C), which may be useful for reference purposes.

2. Spatio-Temporal log-Gaussian Cox processes

A purely spatial intensity function provides the expected number of points per unit area across a given spatial region W when situated at $x \in W$. This becomes a *spatio-temporal* intensity when the observations are time-dependent, such that we now seek to capture the expected number of points per unit area when situated at location $x \in W$, and time $t \in T$. The spatio-temporal LGCP is extremely flexible in that it enables the presence of both fixed and random effects in capturing this space-time behaviour. Here, we describe some fundamental technical details of this modelling framework.

Let $W \subset \mathbb{R}^2$ be an observation window in space and $T \subset \mathbb{R}_{\geq 0}$ be an interval of time of interest. Cases occur at spatio-temporal positions $(x,t) \in W \times T$ according to an inhomogeneous spatio-temporal Cox process, i.e., a Poisson process with a stochastic intensity R(x,t). The number of cases, $X_{S,[t_1,t_2]}$, arising in any $S \subseteq W$ during the interval $[t_1,t_2] \subseteq T$ is then Poisson distributed conditional on R,

$$X_{S,[t_1,t_2]} \sim \text{Poisson}\left\{ \int_S \int_{t_1}^{t_2} R(s,t) \mathrm{d}s \mathrm{d}t \right\}.$$
 (1)

Following Diggle et~al. (2005), the intensity is decomposed multiplicatively as,

$$R(s,t) = \lambda(s)\mu(t)\exp\{\mathcal{Y}(s,t)\}. \tag{2}$$

In Equation 2, the *fixed spatial component*, $\lambda : \mathbb{R}^2 \mapsto \mathbb{R}_{\geq 0}$, is a user-supplied function, proportional to the population at risk at each point in space and scaled so that,

$$\int_{W} \lambda(s) \mathrm{d}s = 1,\tag{3}$$

whilst the fixed temporal component, $\mu: \mathbb{R}_{\geq 0} \mapsto \mathbb{R}_{\geq 0}$, is also a user-supplied function such that,

$$\mu(t) = \lim_{\delta t \to 0} \left\{ \frac{\mathsf{E}[X_{W,\delta t}]}{|\delta t|} \right\}. \tag{4}$$

The function \mathcal{Y} is a Gaussian process, continuous in both space and time. In the nomenclature of epidemiology, the components λ and μ determine the *endemic* spatial and temporal component of the population at risk; whereas \mathcal{Y} captures the residual variation, or the *epidemic* component.

The Gaussian process, \mathcal{Y} , is second order stationary with minimally-parametrised covariance function,

$$cov[\mathcal{Y}(s_1, t_1), \mathcal{Y}(s_2, t_2)] = \sigma^2 r(||s_2 - s_1||; \phi) \exp\{-\theta(t_2 - t_1)\},\tag{5}$$

where $||\cdot||$ is a suitable norm on \mathbb{R}^2 , for instance the Euclidean norm, and $\sigma, \phi, \theta > 0$ are known parameters. In the **lgcp** package, the isotropic spatial correlation function, r, may take one of several forms and possibly require additional parameters (in **lgcp**, this can be selected from any of the compatible models in the function CovarianceFct from the RandomFields package). The parameter σ scales the log-intensity, whilst the parameters ϕ and θ govern the rates at which the correlation function decreases in space and in time, respectively. The mean of the process $\mathcal Y$ is set equal to $-\sigma^2/2$ so as to give $\mathsf E[\exp\{\mathcal Y\}]=1$, hence the endemic/epidemic analogy above.

3. Inference

As in Møller, Syversveen, and Waagepetersen (1998), Brix and Diggle (2001) and Diggle $et^{\sim}al.$ (2005), a discretised version of the above model will be considered, defined on a regular grid over space and time. Observations, X, are then treated as cell counts on this grid. The discrete version of \mathcal{Y} will be denoted Y; since Y is a finite collection of random variables, the properties of \mathcal{Y} imply that Y has a multivariate Gaussian density with approximate covariance matrix Σ , whose elements are calculated by evaluating Equation 5 at the centroids of the spatio-temporal grid cells. Without loss of generality, unit time-increments are assumed and events can be thought of as occurring "at" integer times t. Let X_t denote an observation over the spatial grid at time t, and $X_{t_1:t_2}$ denote the observations at times $t_1, t_1 + 1, \ldots, t_2$. For predictive inference about Y, samples from the conditional distribution of the latent field, Y_t , given the observations to date, $X_{1:t}$ would be drawn, but this is infeasible because the dimensionality of the required integration increases without limit as time progresses. An alternative, as suggested by Brix and Diggle (2001), is to sample from $Y_{t_1:t_2}$ given $X_{t_1:t_2}$,

$$\pi(Y_{t_1:t_2}|X_{t_1:t_2}) \propto \pi(X_{t_1:t_2}|Y_{t_1:t_2})\pi(Y_{t_1:t_2}),$$
(6)

where $t_1 = t_2 - p$ for some small positive integer p. The justification for this approach is that observations from the remote past have a negligible effect on inference for the current state, Y_t .

In order to evaluate $\pi(Y_{t_1:t_2})$ in Equation 6, the parameters of the process Y must either be known or estimated from the data. Estimation of σ , ϕ and θ may be achieved either in a Bayesian framework, or by one of a number of more $ad\ hoc$ methods. The methods implemented in the current version of the **lgcp** package fall into the latter category and are described in Brix and Diggle (2001) and Diggle $et\ al$ (2005). Briefly, this involves matching empirical and theoretical estimates of the second-moment properties of the model. For the spatial covariance parameters σ and ϕ , the inhomogeneous K-function, or g function are used (Baddeley, Møller, and Waagepetersen 2000). The autocorrelation function of the total event-counts per unit time-interval is used for estimating the temporal correlation parameter θ . The estimated parameter values can then be used to implement plug-in-prediction for the latent field Y_t .

lgcp provides only very basic tools for the estimation of $\lambda(s)$ and $\mu(t)$, as described in Section 4.3. The rationale for this is that there are many possible parametric and non-parametric choices implemented in other R packages that could be used to infer the fixed spatial or temporal components of the model: for example in Diggle $et^{\tilde{}}al.$ (2005), the authors use a generalised linear model for $\mu(t)$. What **lgcp** does provide is a flexible framework to allow interface with other packages: $\mu(t)$ can be defined as an arbitrary function, for example the fitted values from the output of a statistical model e.g., glm() or gam(); and $\lambda(s)$ can either be defined as a continuous function of two variables, or as the output of a model onto a fine grid. The in-package estimation routines for $\lambda(s)$ and $\mu(t)$ are both non-parametric, respectively a simple bivariate kernel density estimate and a lowess smoother, and not intended to provide a rigorous solution to the needs of all users. Use of these automatic/interactive procedures is subjective and application specific. Generally speaking, under the 'global' treatment of the fixed components λ and μ , we would intuitively err on the side of over-smoothing rather than under-smoothing these trends. Some numerical evidence in Davies and Hazelton (2012) supports this notion in terms of the subsequent performance of the minimum contrast parameter estimation techniques (see Section 4.4).

3.1. Discretising and the fast-Fourier transform

The first barrier to inference is computation of the covariance matrix, Σ , which even for relatively coarse grids is very large. Fortunately, for stationary covariance functions defined on regular spatial grids of size $2^m \times 2^n$, there exist fast methods for computing this based on the discrete Fourier transform (Wood and Chan 1994). The general idea is to embed Σ in a symmetric circulant matrix, $C = Q\Lambda Q^*$, where Λ is a diagonal matrix of eigenvalues of C, Q is a unitary matrix and * denotes the Hermitian transpose. The entries of Q are given by the discrete Fourier transform. Computation of $C^{1/2}$, which is useful for both simulation and evaluation of the density of Y, is then straightforward using the fact that $C^{1/2} = Q\Lambda^{1/2}Q^*$.

3.2. The Metropolis-adjusted Langevin algorithm

Monte Carlo simulation from $\pi(Y_{t_1:t_2}|X_{t_1:t_2})$ is made more efficient by working with a linear transformation of Y, partially determined by the matrix C as described below. The **lgcp** package returns results pertaining to Y on a grid of size $M \times N \equiv 2^m \times 2^n$ for positive integers m and n, which is extended to a grid of size $2M \times 2N$ for computation (Møller $et^{\sim}al$.

1998). Writing $\Gamma_t = \Lambda^{-1/2} Q(Y_t - \mu)$, the target of interest is given by

$$\pi(\Gamma_{t_1:t_2}|X_{t_1:t_2}) \propto \left[\prod_{t=t_1}^{t_2} \pi(X_t|Y_t)\right] \left[\pi(\Gamma_{t_1}) \prod_{t=t_1+1}^{t_2} \pi(\Gamma_t|\Gamma_{t-1})\right]$$
(7)

where the first term on the right hand side of Equation 7 corresponds to the first bracketed term on the right hand side of Equation 6 and the second bracketed term is the joint density, $\pi(\Gamma_{t_1:t_2})$, which so-factorises due to the Markov property. Since Y, and hence Γ , is an Ornstein-Uhlenbeck process in time, the transition density, $\pi(\Gamma_t|\Gamma_{t-1})$, has an explicit expression as a Gaussian density; see Brix and Diggle (2001).

Since the gradient of the transition density can also be written down explicitly, a natural and efficient MCMC method for sampling from the predictive density of interest (Equation 7), is a Metropolis-Hastings algorithm with a Langevin-type proposal (Roberts and Tweedie 1996),

$$q(\Gamma, \Gamma') = \mathcal{N}\left(\Gamma'; \Gamma + \frac{1}{2}\nabla \log\{\pi(\Gamma|X)\}, h^2\mathbb{I}\right)$$

where N(y; m, v) denotes a Gaussian density with mean m and variance v evaluated at y, \mathbb{I} is the identity matrix and h > 0 is a scaling parameter (Metropolis, Rosenbluth, Rosenbluth, Teller, and Teller 1953; Hastings 1970).

Various theoretical results exist concerning the optimal acceptance probability of the MALA (Metropolis-Adjusted Langevin Algorithm) – see Roberts and Rosenthal (1998) and Roberts and Rosenthal (2001) for example. In practical applications, the target acceptance probability is often set to 0.574, which would be approximately optimal for a Gaussian target as the dimension of the problem tends to infinity. An algorithm of Andrieu and Thoms (2008) for the automatic choice of h, so that this acceptance probability is achieved without disturbing the ergodic property of the chain is implemented in $\lg cp$.

4. Introducing the lgcp package

4.1. An overview of this section

In this section, we present a brief tour of package functionality by means of a walk-through spatio-temporal example. In Section 4.2, reading in and converting data into the required format for inference is discussed. Section 4.3 addresses the issue of estimating $\lambda(s)$ and $\mu(t)$ using **lgcp**'s built in capabilities; the reader should note at the outset that these two quantities would normally be estimated via some other means, as will be discussed. In Section 4.4, we discuss parameter estimation: **lgcp** provides simple minimum-contrast procedures for this task. Then in Section 4.5 and 4.6, we detail respectively the setting up and running of the MCMC algorithm, including: specifying the model, adaptive MCMC, computation of Monte Carlo expectations 'on-line' and possible rotation of the observation window. Lastly, in Section 4.7, we show how to: extract information from a finished MCMC run; plot the results; forecast into the future; handle data dumped to disk; MCMC diagnostics and plotting exceedance probabilities.

4.2. Reading-in and converting data

The generic data-format of interest is (x_i, y_i, t_i) : i = 1, ..., n, where the (x_i, y_i) are the locations and t_i the times of occurrence of events in $W \times (A, B)$, where W is a polygonal observation window and (A, B) the time-interval within which events are observed. In the following example x, y and t are R objects giving the location and time of events and win is a spatstat object of class owin specifying the polygonal observation window (Baddeley and Turner 2005). An example of constructing an appropriate owin object from ESRI shapefiles is given in the package vignette (type vignette("lgcp")).

```
R> data <- cbind(x,y,t)
R> tlim <- c(0,100)
R> win
window: polygonal boundary
enclosing rectangle: [381.7342, 509.7342] x [64.14505, 192.14505] units
```

The first task for the user is to convert this into a space-time planar point pattern object i.e., one of class stppp, provided by lgcp. An object of class stppp is easily created:

```
R> xyt <- stppp(list(data=data,tlim=tlim,window=win))</pre>
```

The second task is to choose a time-scale, and to convert the real-valued times into integer-valued times. These steps are important, as they can affect our ability to estimate the temporal correlation parameter θ , and hence to borrow strength from observations over time: too coarse a discretisation means that data from successive aggregated time points is effectively independent, and the estimation of θ is not possible using the simple methods we suggest in this article. Rescaling time is a simple operation involving multiplying the real-valued xyt\$t by another real number. Since lgcp uses as.integer to convert to integer values, these real-valued times will be rounded-down to the integer below. The function integerise.stppp takes care of this rounding process, and also amends xyt\$tlim, if necessary.

```
R> xyt <- integerise(xyt)
R> xyt

Space-time point pattern
  planar point pattern: 10069 points
window: polygonal boundary
enclosing rectangle: [381.7342, 509.7342] x [64.14505, 192.14505] units
  Time Window : [ 0 , 99 ]
```

Since in this example, the data were simulated on a continuous time-line from time 0 up to 100, integerise.stppp has rounded the upper limit (xyt\$tlim[2]) down: both xyt\$t and xyt\$tlim are now integer vector objects. This ensures that subsequent estimates of $\mu(t)$ will be correctly scaled.

4.3. Estimating the spatial and temporal component

There are many ways to estimate the fixed spatial and temporal components of the log-Gaussian Cox process. The fixed spatial component, $\lambda(s)$, represents the spatial intensity of

events, averaged over time and scaled to integrate to 1 over the observation window W. In epidemiological settings, this typically corresponds to the spatial distribution of the population at risk, although this information may not be directly available. The fixed temporal component, $\mu(t)$, is the mean number of events in W per unit time. Where the relevant demographic information is unavailable to specify $\lambda(s)$ and $\mu(t)$ directly, **lgcp** provides basic functionality to estimate them from the data.

A user may wish to specify parametric models for λ and μ , perhaps estimating them by using spatially and temporally referenced covariates. By outputting the results of such parametric models onto a grid in space, which is the easiest way to handle the fixed spatial component (by creating a spatialAtRisk object directly, see ?spatialAtRisk.fromXYZ), or as a function on the real line, in the case of the fixed temporal component, the user is able to utilise a wide variety of other statistical models in other R packages to estimate λ and μ . The function λ in particular will frequently have the interpretation of something proportional to population density, and hence may not have been estimated by a formal statistical procedure. The authors envisage such an object as being stored directly in R as a spatstat im object.

lgcp uses bilinear interpolation (via the **spatstat** function **interp.im**) to transfer a user supplied $\lambda(s)$ onto the FFT grid ready for analysis. Therefore, for best results, the user should output their estimate of λ onto the grid that will be used in the algorithm, as we will be using a 2km grid in the example, this can be computed with,

R> OW <- selectObsWindow(xyt,cellwidth=2)</pre>

the objects OW\$xvals and OW\$yvals now contain the grid on which the fitting of λ should be projected for best results.

The function lambdaEst is an interactive implementation of a kernel method for estimating $\lambda(s)$ from the data as in the following example:

```
R> den <- lambdaEst(xyt,axes=TRUE)
R> plot(den)
```

This calls an **rpanel** tool (Bowman *et~al.* 2007) for estimating λ (see Figure~1); once the user is happy with the result, clicking on "OK" closes the panel and the kernel density estimate is stored in the R object den of class im (a **spatstat** pixel image object). The estimate of λ can then be plotted in the usual way. The parameters bandwidth and adjust in this GUI relate to the arguments from the **spatstat** function density.ppp; the former corresponds to the argument sigma and the latter to the argument of the same name.

The function lambdaEst is built directly on the density.ppp function and as such, implements a bivariate Gaussian smoothing kernel. The bandwidth is initially that which is automatically chosen by the default method of density.ppp. Since image plots of these kernel density estimates may not have appropriate colour scales, the ability to adjust this is given with the slider 'colour adjustment'. With colour adjustment set to 1, the default image.plot for the equivalent pixel image object is shown and for values less than 1, the colour scheme is more spread out, allowing the user to get a better feel for the density that is being fitted. The colour adjustment parameter raises each cell-wise entry to that power. NOTE: colour adjustment does not affect the returned density and the user should be aware that the returned density will visually appear exactly as displayed when colour adjustment is set equal to 1. lambdaEst does not output to the FFT grid used in the MALA algorithm.

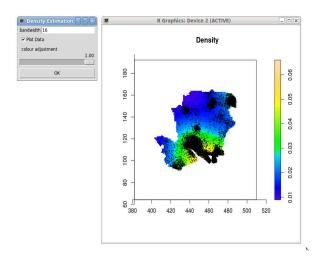

Figure 1: Choosing a kernel density estimate of $\lambda(s)$.

The lgcp package provides methods for coercing pixel-images like den to objects of class spatialAtRisk, which can then be used in parameter estimation and in the MALA algorithm to be discussed later; further useful information on the spatialAtRisk class is provided in Appendix C.

```
R> sar <- spatialAtRisk(den)
SpatialAtRisk object</pre>
```

X range : [382.3742066569,509.094206656898]
Y range : [64.785045372051,191.505045372051]

dim : 100 x 100

For the temporal component, $\mu(t)$, the user must provide an object that can be coerced into one of class temporalAtRisk.

Objects of class temporalAtRisk are non-negative functions of time over an observation time-window of interest, which must be the same as the time-window of the stppp data object, xyt. In some applications (Diggle et~al.~2005), $\mu(t)$ might represent the fitted values of a parametric model for the case counts over time. As it is not possible to provide generic functionality for parametric $\mu(t)$, a simple non-parametric estimate of μ can be generated using the function muEst:

```
R> mut1 <- muEst(xyt)
R> mut1

temporalAtRisk object
function(t){
    if (!any(as.integer(t)==tvec)){
        return(NA)
    }
    return(obj[which(as.integer(t)==tvec)] * scale)
```

```
}
<environment: 0xbb68b08>
attr(,"tlim")
[1] 0 99
attr(,"class")
[1] "temporalAtRisk" "function"
    Time Window : [ 0 , 99 ]
```

In order to retain positivity, muEst fits a locally-weighted polynomial regression estimate (the R function lowess) to the square root of the interval counts and returns the square of this smoothed estimate (see Figure 2). The amount of smoothing is controlled by the lowess argument f which specifies the proportion of points in the plot which influence the smoothed estimate at each value (see ?lowess), for example muEst(xyt,f=0.1). If the user wishes to specify a constant time-trend, $\mu(t) = \mu$, the command

```
R> mut <- constantInTime(xyt)</pre>
```

returns the appropriate temporalAtRisk object, correctly scaled as in Equation 4. The

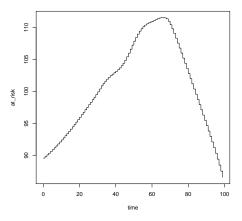

Figure 2: Estimating $\mu(t)$: the output from plot(mut1).

fixed temporal component can be also be supplied either as a vector or as a function that is automatically coerced to a temporalAtRisk object and scaled to achieve the condition in Equation~4.

4.4. Estimating parameters

After estimating $\lambda(s)$ and $\mu(t)$, the next step in the analysis is to estimate the covariance parameters of the process \mathcal{Y} . **lgcp** provides basic moment-based methods for this in the form of **rpanel** GUIs that allow the user to choose σ , ϕ and θ by eye (Bowman et al. 2007). Parameter estimation by eye is both fast and reasonably robust and moreover emphasizes the fact that the underlying methods are $ad\ hoc$. As mentioned above, it is possible to implement principled Bayesian parameter estimation for this model by integrating over the discretised latent-field, Y; this is a planned extension to the package (see Section 5).

The spatial correlation parameters σ and ϕ can be estimated either from the inhomogeneous pair correlation function, g, or the inhomogeneous K function (Baddeley et al. 2000). Following Brix and Diggle (2001) and Diggle et al. (2005), the corresponding functions in gc estimate versions of these two functions by averaging temporally localised versions. The respective commands for doing so are:

```
R> gin <- ginhomAverage(xyt,spatial.intensity=sar,temporal.intensity=mut)
R> kin <- KinhomAverage(xyt,spatial.intensity=sar,temporal.intensity=mut)</pre>
```

The parameters are then estimated using either of the following:

These invoke another call to **rpanel**, which produces the plots in Figure 3. The user's task is to match the orange theoretical function with the black empirical counterpart. The list

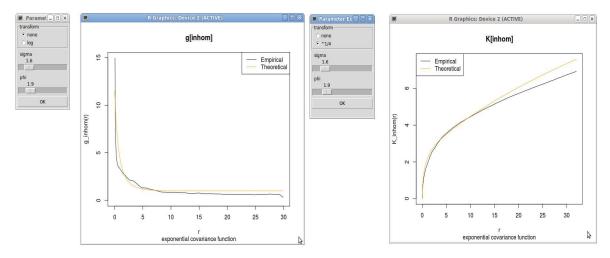

Figure 3: Estimating σ and ϕ : left via the pair correlation function and right via the inhomogeneous K function.

of correlation functions available to the user is given under the help file for the function CovarianceFct from the RandomFields package. For certain classes of covariance function, for example the Matérn or Whittle families, additional parameters are specified by the user via the covpars argument and supplied to spatialParsEst in the same order as they appear in the help file for CovarianceFct. These additional parameters are treated as known constants, and not estimated via a formal nor informal procedure. One reason for this is because some of these parameters are notoriously difficult to estimate, for example, the parameter ν in the Matérn family. A recommended strategy in these cases is to choose between a discrete set of candidate values for the parameter of interest. For example, in the Matérn family the integer part of ν gives the number of times the underlying Gaussian process is mean-square differentiable. The resulting estimated parameters are returned in list objects (e.g., sigmaphi1 or sigmaphi2) with sigmaphi1\$sigma and sigmaphi1\$phi returning the required values of

 σ and ϕ . In the code below, these values have been input as respectively 1.6 and 1.9 as was estimated above. The user has additional control over the minimum contrast estimation, for example the range of evaluation, though sensible defaults are provided automatically by the embedded **spatstat** functions. The initial parameter values appearing in the GUIs are obtained through a simple weighted least-squares optimization procedure, but note that this is not robust, and the user has the option to turn this functionality off via guess=FALSE in the argument list to spatialParsEst.

The temporal correlation parameter, θ , can be estimated using the function thetaEst; this requires σ , ϕ and $\mu(t)$ to have been estimated beforehand. For example, the call

gives the GUI shown in Figure 4. Note that again, in the code below the estimated value of 1.4 has been input manually.

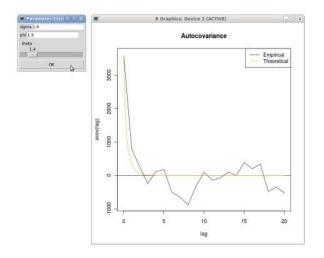

Figure 4: Estimating θ .

4.5. The commands lgcpPredict and lgcpPredictSpatial

The main functions in the **lgcp** package are **lgcpPredict** and **lgcpPredictSpatial**. In this article, we focus on **lgcp**'s spatio-temporal functionality and hence **lgcpPredict**, the rationale being that the 'purely spatial' provided by **lgcpPredictSpatial** is straightforward to understand once familiar with the former. A comparative evaluation of **lgcp**'s spatial capabilities, together with a definition of the statistical model in this case is given in Taylor and Diggle (2012).

This uses an MCMC method to produce samples and summary statistics from the predictive distribution of the discretised process Y, treating previously obtained estimates of $\lambda(s)$, $\mu(t)$, and the covariance parameters as known quantities. The MCMC algorithm is invoked by the command lgcpPredict, whose arguments are as follows:

R> args(lgcpPredict)

```
function (xyt, T, laglength, model.parameters = lgcppars(),
    spatial.covmodel = "exponential",
    covpars = c(), cellwidth = NULL, gridsize = NULL, spatial.intensity,
    temporal.intensity, mcmc.control, output.control = setoutput(),
    missing.data.areas = NULL, autorotate = FALSE, gradtrunc = NULL,
    ext = 2)
```

A pre-emptive note on computation times

With the options set as below: working on a 128×128 FFT grid with six time-points worth of data, and with 120,000 iterations of the MCMC algorithm, the total computation time is around $2\frac{3}{4}$ hours on a 3.2GHz Intel(R) Core(TM) i5 desktop PC with 4Gb RAM. Computation times increase approximately linearly with the addition of additional time-points.

In Taylor and Diggle (2012), using the same PC, the authors compare computation times for the function lgcpPredictSpatial with a computationally equivalent implementation from the INLA package, and they found that 100,000 iterations on a 128 × 128 grid (which gave good predictive performance) ran in around 20 minutes, similar to a call to inla with the option strategy="laplace" outputting results on the same predictive grid as MCMC. The results presented in Taylor and Diggle (2012) question the commonly held notion that MCMC is slow, hard to tune and mixes poorly.

Data and model specification

The argument xyt is the stppp object that contains the data, T is the time-point of interest for prediction (c.f., the time t_2 in Section 3) and laglength tells the algorithm the number of previous time-points whose data should be included, that is the time-interval [T-laglength,T]. Model parameters are set using the model.parameters argument; for example,

```
R> lgcppars(sigma=1.6,phi=1.9,theta=1.4)
```

has the obvious interpretation. The mean of the latent field Y is set to $-\sigma^2/2$ by default. The spatial covariance model and any additional parameters are specified using the spatial.covmodel and covpars arguments; these may come from any of the compatible covariance functions detailed in ?CovarianceFct from the RandomFields package. The physical dimensions of the grid cells can be set using either the cellwidth or gridsize arguments, the second of which gives the number of cells in the x and y directions (these numbers are automatically extended to be a power of two for the fast-Fourier transform). The spatial.intensity and temporal.intensity arguments specify the previously obtained estimates of $\lambda(s)$ and $\mu(t)$, respectively.

It remains to set the MCMC parameters and output controls; these will now be discussed.

Controlling MALA and performing adaptive MCMC

The mcmc.control argument of lgcpPredict specifies the MCMC implementation and is set using the mcmcpars function:

```
R> args(mcmcpars)
```

function (mala.length, burnin, retain, inits = NULL, adaptivescheme)

Here, mala.length is the number of iterations to perform, burnin is the number of iterations to throw away at the start and retain is the frequency at which to store or perform computations; for example, retain=10 performs an action every 10th iteration. The optional argument inits can be used to set initial values of Γ for the algorithm, and is intended for advanced use. The initial values are stored in a list object of length laglength+1, each element being a matrix of dimension $2M \times 2N$. For MCMC diagnostics, discussed in the sequel, the user must dump information from the chain to disk using the dump2dir, discussed below. The MALA proposal tuning parameter h in Section 3.2 must also be chosen. The most straightforward way to do this is to set adaptivescheme=constanth(0.001), which gives h = 0.001. Without a lengthy tuning process, the value of h that optimizes the mixing of the algorithm is not known. One solution to the problem of having to choose a scaling parameter from pilot runs is to use adaptive MCMC (Roberts and Rosenthal 2009; Andrieu and Thoms 2008). Adaptive MCMC algorithms use information from the realisation of an MCMC chain to make adjustments to the proposal kernel. The Markov property is therefore no longer satisfied and some care must be taken to ensure that the correct ergodic distribution is preserved. An elegant method, introduced by Andrieu and Thoms (2008) uses a Robbins-Munro stochastic approximation update to adapt the tuning parameter of the proposal kernel (Robbins and Munro 1951); see below for suggested parameter values for this scheme. The idea is to update the tuning parameter at each iteration of the sampler according to the iterative scheme,

$$h^{(i+1)} = h^{(i)} + \eta^{(i+1)}(\alpha^{(i)} - \alpha_{\text{opt}}), \tag{8}$$

where h(i) and $\alpha^{(i)}$ are the tuning parameter and acceptance probability at iteration i and $\alpha_{\rm opt}$ is the target acceptance probability. For Gaussian targets, and in the limit as the dimension of the problem tends to infinity, an appropriate target acceptance probability for MALA algorithms is $\alpha_{\rm opt} = 0.574$ (Roberts and Rosenthal 2001). The sequence $\{\eta^{(i)}\}$ is chosen so that $\sum_{i=1}^{\infty} \eta^{(i)}$ is infinite but for some $\epsilon > 0$, $\sum_{i=1}^{\infty} \left(\eta^{(i)}\right)^{1+\epsilon}$ is finite. These two conditions ensure that any value of h can be reached, but in a way that maintains the ergodic behaviour of the chain. One class of sequences with this property is,

$$\eta^{(i)} = \frac{C}{i^{\zeta}},\tag{9}$$

where $\zeta \in (0, 1]$ and C > 0 (Andrieu and Thoms 2008).

The tuning constants for this algorithm are set with the function andrieuthomsh.

R> args(andrieuthomsh)

function (inith, alpha, C, targetacceptance = 0.574)

In the above, inith is the initial value of h and the remaining arguments correspond to their counterparts in the text above. In our experience of using this algorithm, we have found it to be very robust, and have used the values inith=1, alpha=0.5 and C=1 successfully across a variety of scenarios without any difficulty.

The advanced user can also write their own adaptive scheme, detailed examples of which are provided in the package vignette. Briefly, writing an adaptive MCMC scheme involves writing

two functions to tell R how to initialise and update the values of h. This may sound simple, but it is crucial that these functions preserve the correct ergodic distribution of the MCMC chain, an appreciation of these subtleties is **essential** before any attempt is made to code such schemes.

Specifying output

By default, lgcpPredict computes the Monte Carlo mean and variance of Y and the mean and variance of $exp{Y}$ (the relative risk) for each of the grid cells and time intervals of interest. Additional storage and online computations are specified by the output.control argument and the setoutput function:

R> args(setoutput)

function (gridfunction = NULL, gridmeans = NULL)

The option gridfunction is used to declare general operations to be performed during simulation (for example, dumping the simulated Ys to disk), whilst user-defined Monte Carlo averages are computed using gridmeans. A complete run of the MALA chain can be saved using the dump2dir function:

R> args(dump2dir)

function (dirname, lastonly = TRUE, forceSave = FALSE)

The user supplies a character string, dirname, giving the name of a directory in which the results are to be saved. The other arguments to dump2dir are, respectively, an option to save only the last grid (i.e., the time T grid) and to bypass a safety message that would otherwise be displayed when dump2dir is invoked. The safety message warns the user of disk space requirements for saving. For example, on a 128 × 128 output grid using 5 days of data, 1000 simulations from the MALA will take up approximately 625 megabytes.

The option lastonly in the functions dump2dir and MonteCarloAverage (see below) is set to TRUE by default, this means that only information from the last time point is saved or manipulated. The main reason for doing this is that by definition of the model, statistical interest is focussed on inference for the last time point, T. It is assumed that the information from lagged time points contributes to predictions at time T, but that information from further in the past has only negligible effect. Setting lastonly=TRUE also has the advantage that the algorithm runs faster, but should it be of interest to examine predictions at lagged time points, the option should be set to FALSE.

Another option is to compute Monte Carlo expectations,

$$\mathsf{E}_{\pi(Y_{t_1:t_2}|X_{t_1:t_2})}[g(Y_{t_1:t_2})] = \int_W g(Y_{t_1:t_2})\pi(Y_{t_1:t_2}|X_{t_1:t_2})\mathrm{d}Y_{t_1:t_2},\tag{10}$$

$$\approx \frac{1}{n} \sum_{i=1}^{n} g(Y_{t_1:t_2}^{(i)}) \tag{11}$$

where g is a function of interest, $Y_{t_1:t_2}^{(i)}$ is the *i*th retained sample from the target and n is the total number of retained iterations. For example, to compute the mean of $Y_{t_1:t_2}$, set

 $g(Y_{t_1:t_2}) = Y_{t_1:t_2}$. The output from such a Monte Carlo average would then be a set of $t_2 - t_1$ grids, each cell of which is equal to the mean over all retained iterations of the algorithm. In the context of setting up the gridmeans option to compute the Monte Carlo mean, the user would define a function g as

```
R> gfun <- function(Y){
    return(Y)
}</pre>
```

and input this to the MALA run using the function MonteCarloAverage,

R> args(MonteCarloAverage)

function (funlist, lastonly = TRUE)

Here, funlist is either a list or a character vector giving the names of the function(s) g. The specific syntax for the example above would be a call of the form MonteCarloAverage("gfun"). The functions of interest (e.g., gfun above) are assumed to act on each of the individual grids, Y_{t_i} , and return a grid of the same dimension.

A second example arises in epidemiological studies where it is of clinical interest to know whether, at any location s, the ratio of current to expected risk exceeded a pre-specified intervention threshold; see, for example, Diggle $et^{\sim}al$. (2005), where real-time predictions of relative risk are presented as maps of exceedance probabilities, $P\{\exp(Y_t) > k | X_{1:t}\}$ for a prespecified threshold k. Any such exceedance probability can be expressed as an expectation,

$$\mathsf{P}[\exp(Y_{t_1:t_2}) > k] = \mathsf{E}_{\pi(Y_{t_1:t_2}|X_{t_1:t_2})}\{\mathbb{I}[\exp(Y_{t_1:t_2}) > k]\} = \frac{1}{n} \sum_{i=1}^n \mathbb{I}[\exp(Y_{t_1:t_2}^{(i)}) > k],$$

where I is the indicator function, and a Monte Carlo approximation can therefore be computed on-line using MonteCarloAverage.

The corresponding function g is

$$g(Y_{t_1:t_2}) = \mathbb{I}[\exp(Y_{t_1:t_2}) > k].$$

Exceedance probabilities are made available directly within **lgcp** by the function **exceedProbs**. To make use of this facility, the user specifies the thresholds of interest, for example 1.5, 2 and 3, then creates a function to compute the required exceedances:

```
R > exceed <- exceedProbs(c(1.5,2,3))
```

The object exceed is now a function that returns the exceedance probabilities as an array object of dimension $M \times N \times 3$. This function can be passed through to the gridmeans option, together with the previously defined gfun, via gridmeans=MonteCarloAverage(c("gfun","exceed"). The lgcpPredict function then returns point-wise predictive means and three sets of exceedance probabilities. Note that, the example function gfun is included for illustrative purposes only and is in fact redundant, as lgcpPredict automatically returns the predictive mean (as well as the variance) of Y.

Rotation

Testing whether estimation can proceed more efficiently in a rotated space is described in detail in Appendix A. Note that if the data and observation window are rotated, then λ must also be rotated to retain compatibility. If λ was estimated in the original frame of reference and autorotate=TRUE, then lgcpPredict will automatically rotate λ if it is computationally worthwhile to do so. For λ specified as a grid, either directly or via an object of class im, then a small amount of information loss occurs in the rotation because the square cells in the original orientation become misaligned with the axes in the rotated space and vice-versa. If λ is specified by a continuous function, then no such loss occurs.

Gradient truncation

One undesirable property of the Metropolis-adjusted Langevin algorithm is that the chain is prone to taking very long excursions from the mode of the target; this behaviour can have a detrimental effect on the mixing of the chain and consequently on any results. The tendency to make long excursions is caused by instability in the computation of the gradient vector, but the issue is relatively straightforward to rectify without affecting convergence properties (Møller et~al. 1998). The key is to truncate the gradient vector if it becomes too large. If gradtrunc=NULL, then an appropriate truncation is automatically selected by the code. With gradtrunc=Inf, no gradient truncation occurs.

As far as the authors are aware, there are no published guidelines for selecting this truncation parameter. The current version of the lgcp package uses the maximum achieved gradient over a set of 100 independent realisations of $\Gamma_{t_1:t_2}$.

4.6. Running

When all of the above options have been specified, the MALA algorithm can be called as follows:

The above call assumes that the spatial covariance model is exponential, that no rotation is to be performed and that the user wishes to have lgcpPredict compute an appropriate gradient truncation automatically. The arguments spatial.intensity and temporal.intensity

relate to the spatial and temporal intensities, estimated in Section 4.3; note that the chosen temporal model is constant in time. Recall that the option lastonly is by default set to TRUE in both MonteCarloAverage and dump2dir.

The simulated example uses data from times 45 to 50 inclusive, 120,000 iterations, of which the first 20,000 are treated as burn-in, and retains every 100th sample. For diagnostic checking, a sample of MCMC Γ -chains is also saved for each of five randomly selected grid-cells. The observation window is approximately 100km square, so the specified cell width of 2km (given in the same units as used in the object xyt) gives an output grid of size 64×64 , i.e., computation is carried out on a 128×128 grid. The complete run is saved to disk and exceedance probabilities are computed for the last time-point only.

During simulation, a progress bar is displayed giving the percentage of iterations completed.

It is possible at the start of a run that the user may be confronted by a warning message like Time 48: 5 data points lost due to discretisation. This means that there are points close to the edge of the polygonal observation window that lie outside the computational grid. Critical information is only lost in any subsequent conditional predictions if we were specifically interested in behaviour close to these areas, in which case there are two options. The easiest solution assuming that prediction in these areas is important, but bears additional computational expense and may not fix the warnings, is to use a finer grid resolution. The alternative, and more rigorous approach is to extend the true observation window by surrounding it with a buffer, pre-compute the FFT grid on the buffered window via selectObsWindow as discussed earlier and then tailor a spatialAtRisk object onto the buffered window to adjust for these edge effects on the true observation window.

4.7. Post-processing

The stored output lg is an object of class lgcpPredict. Typing lg into the console prints out information about the run:

```
R> 1g
```

lgcpPredict object.

General Information

FFT Gridsize: [128 , 128]

Data:

Time | 45 46 47 48 49 50 Counts | 98 345 106 100 73 67

Parameters: sigma=1.6, phi=1.9, theta=1.4

Dump Directory: C:/MyDirectory/

Grid Averages:

Function Output Class exceed array

Time taken: 2.77 hours

MCMC Information

Number Iterations: 120000

Burn-in: 20000 Thinning: 100 Mean Acceptance: 0.574

Adaptive Scheme: andrieuthomsh

Last h: 0.00904236148499419

Information returned includes the FFT grid size used in computation; the count data for each day; the parameters used; the directory, if specified, to which the simulation was dumped; a list of MonteCarloAverage functions together with the R class of their returned values; the time taken to do the simulation; and information on the MCMC run.

Extracting information

The cell-wise mean and variance of Y computed via Monte Carlo can always be extracted using meanfield(lg) and varfield(lg), respectively. The calls rr(lg), serr(lg), intens(lg) and seintens(lg) return respectively the Monte Carlo mean relative risk (the mean of $exp\{Y\}$), the standard error of the relative risk, the estimated cell-wise mean Poisson intensity and the standard error of the Poisson intensity. The x and y coordinates for the grid output are obtained via xvals(lg) and yvals(lg). The returned object from calls like meanfield, varfield or intens are objects of class lgcpgrid, so the command,

R> intensity <- intens(lg)</pre>

creates an lgcpgrid object containing the mean Poisson intensities. Then, for example intensity\$grid[[1]] returns the Poisson intensities relating to the first time aggregated point, with an appropriate (x,y) grid available using xvals(lg) and yvals(lg). Similarly, intensity\$grid[[2]] returns the intensities from the second aggregated time point. lgcpPredict not only produces predictions for grid locations inside the observation window, but also it produces predictions for cells outside the observation window too. This is because we define $\lambda(s) = 0$ for $s \notin W$: we expect no counts, and observe no counts in these cells. The values returned by intensity\$grid[[1]] are therefore stored in a rectangular matrix. To see which of these cells lies inside the observation window, use the following command,

R> fftgr <- discreteWindow(lg)</pre>

which returns a logical matrix of the same dimension as <code>intensity\$grid[[1]]</code>. These commands give the user the freedom to manipulate the outputs from an MCMC run and produce their own plots, for example. Should the user prefer <code>list</code> or <code>array</code> versions of the <code>lgcpgrid</code> objects, conversion is possible via the functions <code>as.list</code> and <code>as.array</code>.

If invoked, the commands gridfun(lg) and gridav(lg) return respectively the gridfunction and gridmeans options of the setoutput argument of the lgcpPredict function, whilst window(lg) returns the observation window.

Note that the structure produced by gav <- gridav(lg) is a list of length 2. The first element of gav, retrieved with gav\$names, is a list of the function names given in the call to MonteCarloAverage. The second element, gav\$output, is a list of the function outputs; the *i*th element in the list being the output from the function corresponding to the *i*th element of gav\$names. To return the output for a specific function, use the syntax gridav(lg,fun="exceed"), which in this case returns the exceedance probabilities, for example.

Plotting

Plots of the Monte Carlo mean relative risk and standard errors can be obtained with the commands:

```
R> plot(lg,xlab="x coordinate",ylab="y coordinate")
R> plot(lg,type="serr",xlab="x coordinate",ylab="y coordinate")
```

These commands produce a series of plots corresponding to each time step under consideration; the plots shown in Figure 5 are from the last time step, time 50.

To plot the mean Poisson intensity instead of the relative risk, the optional argument type can be set in the above:

```
R> plot(lg,type="intensity",xlab="x coordinate",ylab="y coordinate")
```

The cases for each time step are also plotted by default.

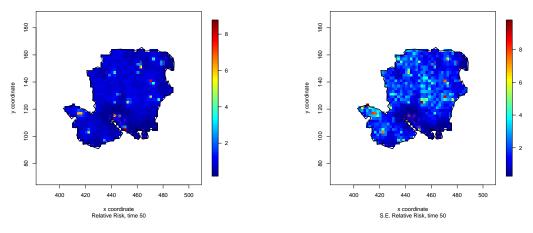

Figure 5: Plots of the Monte Carlo mean relative risk (left) and associated standard errors (right).

It was also suggested by an anonymous referee, that a user could make use of the **spacetime** and **xts** packages for plotting and manipulating data and model outputs from **lgcp** (Pebesma 2012; Ryan and Ulrich 2012).

Forecasting

It is of statistical and epidemiological interest to be able to forecast beyond the time frame

of an analysis, that is to be able to forecast the Poisson intensity,

$$A\lambda(s)\mu(T+k)\exp\{Y(s,T+k)\}$$

where A is the cell area. **lgcp** provides functionality to be able to construct estimates of this together with its approximate variance via the function **lgcpForecast**.

The object fcast now contains the predicted means and variance of Y, the relative risk and Poisson intensities for times 51, 53, 55 and 60. The approximate variances are computed ignoring spatial correlation. We note that should information have been dumped to disk, then it would possible to produce a Monte Carlo estimate of the forecast distribution of Y, the relative risk and Poisson intensities, which would be exact but computationally intensive to compute. Note that a temporal.intensity object must be provided as the temporalAtRisk object used in the MCMC step may not be valid for time points beyond time T. In the above example, we assume that for the forecast time-frame there will be 100 cases per time point on average.

NetCDF

The **lgcp** package provides functions for accessing and performing computations on MCMC runs dumped to disk. Because this can generate very large files, **lgcp** uses the cross-platform **NetCDF** file format for storage and rapid data access, as provided by the package **ncdf** (Pierce 2011). Access to subsets of these stored data is via a file indexing system, which removes the need to load the complete data into memory.

Subsets of data dumped to disk can be accessed with the extract function:

$$R > subsamp < -extract(lg, x=c(4,10), y=c(32,35), t=1, s=-1)$$

which returns an array of dimension $7 \times 4 \times 1 \times 1000$ (recall there were 1000 retained iterations). The arguments x and y refer to the range of x and y indices of the grid of interest whilst t specifies the time points of interest. Note, however, that in this example times 45 through 50 were used for prediction, and t=1 here in fact refers to the sixth of these time-points, i.e., time 50, since the option lastonly was set to TRUE by default. Finally, s=-1 stipulates that all simulations are to be returned. More generally, each argument of extract can be specified either as a range or set equal to -1, in which case all of the data in that dimension are returned. The extract function can also extract MCMC traces from individual cells using, for example, extract(lg,x=37,y=12,t=1).

Should the user wish to extract data from a polygonal subregion of the observation window, this can be achieved with the command

```
R> subsamp2 <- extract(lg,inWindow=win2,t=1)</pre>
```

where win2 is a polygonal observation window defined below. Here, win2 had been selected using the following commands:

```
R> plot(window(lg))
R> win2 <- clickpoly(add=TRUE)</pre>
```

The first of the above commands plots the observation window, whilst the second is a **spat-stat** function for drawing polygonal **owin** objects manually. The user could also specify the **extract** argument **inWindow** directly using a **spat-stat owin** object.

If the user decides that some other summary than those specified by the gridmeans option is of interest, this can easily be computed from the stored data (c.f., Section 4.5.4) The syntax is then slightly different, as in the following example that computes the same exceedances in Section 4.5.4:

R> ex <- expectation(obj=lg,fun=exceed)</pre>

Alternatively, cell-wise quantiles of *functions* of the stored data can also be retrieved and plotted:

```
R> qt <- quantile(lg,c(0.5,0.75,0.9),fun=exp)
R> plot(qt,xlab="X coords",ylab="y coords")
```

As for the extract function above, quantiles can also be computed for smaller spatial observation windows. The indices of any cells of interest in these plots can be retrieved by typing identify(lg). Cells are then selected via left mouse clicks in the graphics device, selection being terminated by a right click.

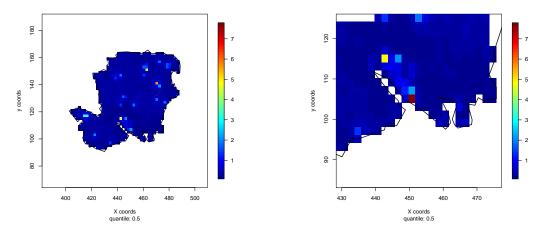

Figure 6: Plot showing the median of relative risk (obtained using fun=exp as in the text) computed from the simulation. Left: quantiles computed for whole window. Right: zooming in on the lower area of the map, representing the cities of Southampton and Portsmouth. Greater detail is available by initially performing the simulation on a finer grid.

Lastly, Linux users can benefit from the software Noview, available from http://meteora.ucsd.edu/~pierce/noview_home_page.html, which provides fast visualisation of NetCDF files. Figure~7 shows a screen-shot, with the control panel (left), an image of one of the sampled grids (top right) and several MCMC chains (bottom right), which are obtained by clicking on the sampled grids; up to five chains can be displayed at a time. There are

equivalent tools for Windows users e.g., Intel® Array Visualizer (http://www.intel.com/cd/software/products/asmo-na/eng/compilers/226277.htm).

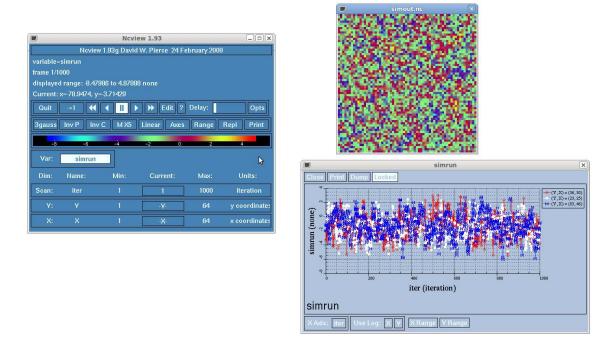

Figure 7: Viewing a MALA run with software netview.

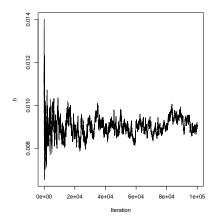

MCMC diagnostics

MCMC diagnostics for the chain are based on the full output from data dumped to disk (see Section 4.7.4). The hvals command returns the value of h used at each iteration in the algorithm, the left hand plot in Figure 8 shows the values of h for the non-burn-in period of the chain; the adaptive algorithm was initialised with h=1, which very quickly converged to around h=0.009.

```
R> plot(hvals(lg)[20000:120000], type="l", xlab="Iteration", ylab="h") R> tr <- t(extract(lg, x=c(6,10), y=32, t=1, s=-1)) # a 1000 by 5 matrix, # with some attributes. R> matplot(tr, type="l", xlab="Iteration", ylab="Y")
```

Trace plots are shown in the right-hand panel of Figure $\tilde{8}$. Note that these are the trace plots for Y, as opposed to Γ To plot the autocorrelation function, the standard R function can be used. For example, acf(tr[,1]) gives the acf of the first extracted chain.

There are a number of R packages for handling MCMC output, for example **coda** (Plummer, Best, Cowles, and Vines 2006). **lgcp** does not provide an interface for working with these packages because the size of the output dumped to disk is potentially so large. It is possible to interface with these packages manually by extracting smaller subsets of data, and converting them to the appropriate format, but this is not dealt with here.

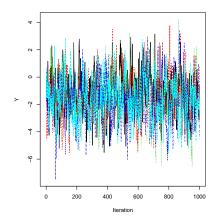

Figure 8: MCMC diagnostic plots. Left: plot of values of h taken by the adaptive algorithm. Right: trace plots of the saved chains from five grid cells.

Plotting exceedance probabilities

Recall that the object exceed, defined above, was a function with an attribute giving a vector of thresholds to compute cell-wise exceedance probabilities at each threshold. A plot can be produced either directly from the lgcpPredict object,

R> plotExceed(lg, fun = "exceed")

or, equivalently, from the output of an expectation on an object dumped to disk:

R> plotExceed(ex[[1]], fun = "exceed",lgcppredict=lg)

Recall also that the option lastonly=TRUE was selected for MonteCarloAverage, hence ex[[1]] in the second example above corresponds to the same set of plots as for the first example. The advantage of computing expectations from files dumped to disk is flexibility. For example, if the user now wanted to plot the exceedances for day 49, this is simply achieved by replacing ex[[6]] with ex[[5]]. Also, exceedances for a new set of thresholds can be computed by creating, for example, a new function by the command exceed2 <-exceedProbs(c(2.3,4)). An example of the resulting output is given in Figure 9.

5. Future extensions

This article has described how **lgcp** may be used to fully specify, fit, and simulate from, i.e., predict conditional on observed data, a spatio-temporal log-Gaussian Cox process on \mathbb{R}^2 . A substantial volume of novel code, such as access to fast-Fourier transform methods needed in simulation and the first open-source R implementation of the Metropolis-adjusted Langevin algorithm for this target, has been instrumental in the development of this package. **lgcp** also has functionality not discussed in this article including methods for handling missing spatial data over time, the approximation of Gaussian fields by Gaussian Markov random fields and prediction for 'spatial-only' log Gaussian Cox processes (Taylor and Diggle 2012).

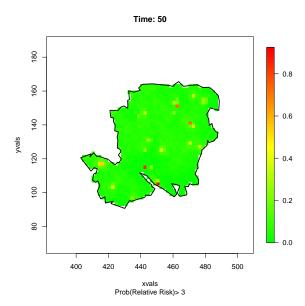

Figure 9: Plot showing the cellwise probability (colour coded) that the relative risk is greater than 3.

The initial motivation for this work was disease surveillance as performed by Diggle et~al. (2005), and it is this application which has driven the core functionality for initial release (at the time of writing, **lgcp** is at version 0.9-4). A list of possible extensions to **lgcp** includes: the ability to include spatial and temporally referenced covariates into the MCMC scheme; to perform principled Bayesian parameter inference (both currently under development); and to handle applications where covariate information is available at differing spatial resolutions. Finally, in the spatio-temporal setting, it is of further interest to include the ability to handle non-separable correlation structures; see for example Gneiting (2002); Rodrigues and Diggle (2010).

6. Acknowledgements

The population data used in this article was based on real data from project AEGISS (Diggle et~al.~2005). AEGISS was supported by a grant from the Food Standards Agency, U.K., and from the National Health Service Executive Research and Knowledge Management Directorate.

A. Rotation

The MALA algorithm works on a regular square grid placed over the observation window. The user is responsible for providing a physical grid size on which to perform estimation/prediction. The gridded observation window is then extended automatically to obtain a $2^m \times 2^n$ grid on which the simulation is performed. By default, the orientation of this extended grid is the same as the object win. If the observation window is elongated and set at a diagonal, then some loss of efficiency that would occur as a consequence of redundant computation at irrelevant

locations can be recovered by rotating the coordinate axes and performing the computations in the rotated space.

To illustrate this, suppose xyt2 is an stppp object with such an elongated and diagonally oriented window (see Figure~10). The function roteffgain displays whether any efficiency can be gained by rotation; clearly this not only depends on the observation window, but also on the size of the square cells on which the analysis will be performed. In the example below, the user wishes to perform the analysis using a cell width of 25km (corresponding to cellwidth=25000 in the code below):

R> roteffgain(xyt2, cellwidth=25000)

```
By rotating the observation window, the efficiency gain would be: 200%, see ?getRotation.stppp
NOTE: efficiency gain is measured as the percentage increase in FFT grid cells from not rotating compared with rotating
[1] TRUE
```

The routine returns FALSE if there is no 'efficiency gain'. Note that the efficiency gain is not a reflection on computational speed, but rather a measure of how many fewer cells the MALA is required to use; this is illustrated in Figure 10. As a technical aside, a better measure would be a ratio of mixing times for the MCMC chains based on unrotated and rotated windows; however, as the mixing time depends on how well the MALA has been tuned, it is not clear how this can be estimated accurately.

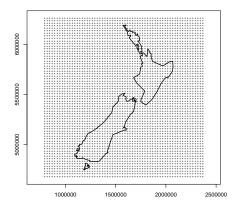

Having ascertained whether rotation is advantageous, the optimally rotated data, observation window and rotation matrix can be retrieved using the function getRotation. For prediction using lgcpPredict, there is also an autorotate option: this allows the user to perform MALA on a rotated grid with minimal input so long as rotation leads to a gain in efficiency. If the model is fitted using a rotated frame, then the predictions will also be returned in this frame: this means that in the original orientation the output will be on a grid misaligned to the original axes. The lgcp package provides methods for the generic function affine so that stppp and spatialAtRisk objects can be rotated manually.

B. Simulating data

The **lgcp** package also provides an approximate simulation tool for drawing samples from the model in Equation~1. Simulation minimally requires an observation window, a range of times over which to simulate data, spatial and temporal intensity functions λ and μ , a cell width for the discretisation and a set of spatial/temporal model parameters together with a choice of spatial covariance model.

The code below simulates data from a log-Gaussian Cox process on the observation window from the example in the text above. The function tempfun is coerced into a temporalAtRisk object and defines the temporal trend. Any appropriately defined temporalAtRisk object can be used here. Similarly, spatial.intensity can either be an object of class spatialAtRisk or one that can be coerced to one.

```
R> W <- xyt$window
R> tempfun <- function(t){return(100)}</pre>
```

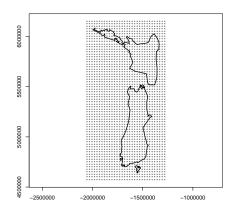

Figure 10: Illustrating the potential gain in efficiency by rotating the observation window. Left plot: the selected grid without rotation. Right plot: the optimally rotated grid.

Note that the finer the grid resolution, the more accurately will the process be simulated, and that smaller values of ϕ require a finer discretisation. A warning is issued if the algorithm thinks the chosen cell width is too large. The discretisation in time is chosen automatically by the algorithm.

C. Handling the SpatialAtRisk class

This section illustrates the available commands for converting between different types of R objects that can be used to describe $\lambda(s)$. Conversion methods are provided for objects from the packages **spatstat** (Baddeley and Turner 2005), **sp** (Bivand $et^{\tilde{}}al.$ 2008) and **sparr** (Davies, Hazelton, and Marshall 2011). These are illustrated in Figure 11. For the purposes of parameter estimation, Figure 12 shows the different **spatialAtRisk** objects that can be converted into an appropriate format (i.e., a **spatstat** im object).

There is also a function to convert from fromXYZ-type spatialAtRisk objects to sp objects of class SpatialGridDataFrame: as.SpatialGridDataFrame(obj,...). Lastly, fromFunction-type can be converted to fromXYZ-type spatialAtRisk objects using the as.fromXYZ function. Note that if a spatialAtRisk object is specified via a function, then it is the user's responsibility to ensure that the function integrates to 1 over the observation window; one way to bypass this problem is to convert the function to an spatialAtRisk object of fromXYZ-type.

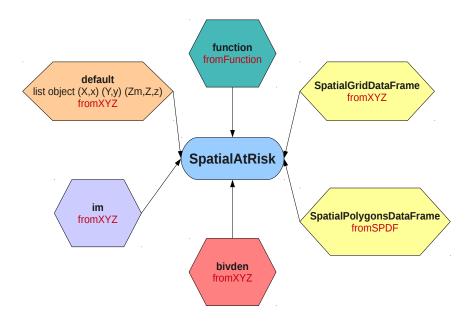

Figure 11: Conversion to spatialAtRisk objects. By default, SpatialAtRisk looks for a list-type object, but other objects that can be coerced include spatstat im objects, function objects, sp SpatialGridDataFrame and SpatialPolygonsDataFrame objects and sparr bivden objects. The text in red gives the type of spatialAtRisk object created.

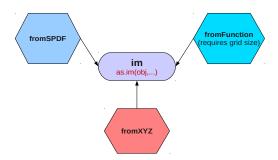

Figure 12: Conversion to **spatstat** objects of class im; these are useful for parameter estimation, in each case a call to the function as.im(obj,...) will perform the coercion.

D. Additional Material for Vignette

D.1. Handling Shapefiles

Here we show how to read in and convert shapefiles for use in lgcp. Boundary files for Wales can be obtained from the Great Britain data files from the GADM (http://www.gadm.org/country) website. The following script will download the level 1 (England, Scotland, Wales, Northern Ireland) and level 2 (counties and regions) data in .RData format, and put them in a temporary directory:

The first polygon needed is the observation window, which is the boundary of Cymru (in English, "Wales"), so it is extracted and converted with the following:

```
# load as object 'gadm'
load(file.path(td,"GBR_adm1.RData"))
# extract the Wales polygons
cymru_border <- gadm[gadm$NAME_1=="Wales",]
# convert to OS Grid reference
cymru_border <- spTransform(cymru_border,CRS("+init=epsg:27700"))
# supress some warnings
spatstat.options(checkpolygons = FALSE)
# convert to owin, and simplify
W <- as(cymru_border,"owin")
W <- simplify.owin(W,dmin=2000)
spatstat.options(checkpolygons = TRUE)</pre>
```

The transformation to OS Grid units is done so that the resulting locations have valid Euclidean distances, which is not the case with latitude-longitude coordinates.

Note that the simplify.owin step is fairly crucial in this example. Without simplifying the observation window, some of the later internal routines can run for a LONG time.

Next, the county-level data are loaded, Wales extracted, and population counts attached to the county polygons:

```
data(wpopdata) # obtained from ONS, population in thousands
load(file.path(td,"GBR_adm2.RData"))
cymru <- gadm[gadm$NAME_1=="Wales",]
cymru <- spTransform(cymru,CRS("+init=epsg:27700"))</pre>
```

```
idx <- match(wpopdata$ID,cymru$ID_2)
cymru$atrisk <- wpopdata$Mid.2010[idx]</pre>
```

D.2. More Complex Temporal-At-Risk Models

This section gives an example of a more complex temporalAtRisk model.

In the previous simulations the temporal trend was set to a constant over time. In Diggle et $^{\sim}al.$ (2005) a more complex model is used which incorporates a linear increasing trend, a seasonal pattern, and a day-of-the-week effect. This can be replicated here by passing an appropriate function to the temporalAtRisk function:

where the various constants come from fitting a GLM to the calibration data.

E. Advanced use of lgcp

E.1. Writing Adaptive MCMC schemes

There are two generic functions to consider when writing adaptive MCMC routines: initialiseAMCMC and updateAMCMC, these respectively define the initialisation and the updating procedures for the adaptive scheme of interest. The task of the user is therefore to tell lgcpPredict what value of h to use at iteration 1, and how to update it. lgcp has two schemes built in: constanth and andrieuthomsh detailed below.

A 'Simple' Example: constanth

This example shows how the scheme constanth was implemented. This is not really an adaptive MCMC scheme and just returns the (fixed) value of h set by the user. In lgcpPredict, this 'adaptive' scheme would be specified using adaptivescheme=constanth(0.01) in the mcmc.control argument and would have the effect of returning h=0.01 at each iteration of the MCMC.

The user is required to write three functions: constanth, and for compatibility with the S3 implementation of this framework, initialiseAMCMC.constanth and updateAMCMC.constanth; these functions are detailed below.

```
constanth <- function(h){
   obj <- h
    class(obj) <- c("constanth","adaptivemcmc")
   return(obj)
}
initialiseAMCMC.constanth <- function(obj,...){
   return(obj)
}
updateAMCMC.constanth <- function(obj,...){
   return(obj)
}</pre>
```

When called, the first of these functions creates an object of super-class **constanth**, this is just a numeric with a class attribute attached. The other two functions simply return the value of h specified by the user at appropriate positions in the code MALAlgcp.

A More Complex Example: and rieuthomsh

The second example shows how to implement a rather neat method of Andrieu and Thoms (2008). A Robbins-Munro stochastic approximation update is used to adapt the tuning parameter of the proposal kernel (Robbins and Munro 1951). The idea is to update the tuning parameter at each iteration of the sampler:

$$h^{(i+1)} = h^{(i)} + \eta^{(i+1)} (\alpha^{(i)} - \alpha_{\text{opt}}),$$

where h(i) and $\alpha^{(i)}$ are the tuning parameter and acceptance probability at iteration i and $\alpha_{\rm opt}$ is a target acceptance probability. For Gaussian targets, and in the limit as the dimension of the problem tends to infinity, an appropriate target acceptance probability for MALA algorithms is 0.574 (Roberts and Rosenthal 2001). The sequence $\{\eta^{(i)}\}$ is chosen so that $\sum_{i=0}^{\infty} \eta^{(i)}$ is infinite whilst $\sum_{i=0}^{\infty} \left(\eta^{(i)}\right)^{1+\epsilon}$ is finite for $\epsilon > 0$. These two conditions ensure that any value of h can be reached, but in a way that maintains the ergodic behaviour of the chain. One class of sequences with this property is,

$$\eta^{(i)} = \frac{C}{i^{\alpha}},$$

where $\alpha \in (0, 1]$ and C > 0 (Andrieu and Thoms 2008).

An adaptivescheme implementing this algorithm must therefore know what value of h to start with, the values of the parameters α and C and the target acceptance probability, hence the choice of arguments for the function and rieuthomsh in the code below:

```
andrieuthomsh <- function(inith,alpha,C,targetacceptance=0.574){</pre>
```

```
if (alpha<=0 | alpha>1){
    stop("parameter alpha must be in (0,1]")
}
if (C<=0){
    stop("parameter C must be positive")
}
obj <- list()
obj$inith <- inith
obj$alpha <- alpha
obi$C <- C
obj$targetacceptance <- targetacceptance
itno <- 0 # iteration number, gets reset after burnin
incrit <- function(){</pre>
    itno <<- itno + 1
restit <- function(){</pre>
    itno <<- 0
}
obj$incritno <- incrit
obj$restartit <- restit
curh <- inith # at iteration 1, the current
               # value of h is just the initial value
hupdate <- function(){</pre>
    curh <<- exp(log(curh) + (C/(itno^alpha))*</pre>
         (get("ac",envir=parent.frame(2))-targetacceptance))
reth <- function(){</pre>
    return(curh)
}
obj$updateh <- hupdate
obj$returncurh <- reth
class(obj) <- c("andrieuthomsh", "adaptivemcmc")</pre>
return(obj)
```

This function returns an object of super-class and rieuthomsh, which is a list object consisting of the parameters specified by the user and additionally some internal functions that are responsible for the updating. Note that in updateAMCMC and rieuthomsh, the internal functions are simply called, and therefore it is these internal functions that actually define the adaptive scheme. The internal functions, incrit, restit, hupdate and reth perform respectively the following tasks: increase the internal iteration counter, restart the internal iteration counter, do the actual updating of h and lastly return the current value of h.

Note that from a developmental point of view, the piece of code,

}

```
get("ac",envir=parent.frame(2))
```

gets the current acceptance probability, which in MALAlgcp is stored as an object called ac. To initialise the scheme, the method for initialiseAMCMC simply returns the initial value of h set by the user:

```
initialiseAMCMC.andrieuthomsh <- function(obj,...){
    return(obj$inith)
}</pre>
```

In the update step, the internal functions created by the andrieuthomsh function are invoked. The procedure is as follows (1) information about the mcmc loop is retrieved using get("mcmcloop",envirparent.frame())=, then if the algorithm has just come out of the burn in period, the adaptation of h is restarted¹, next the internal iteration counter is incremented, and lastly the value of h is updated and returned (the procedures for these internal functions are printed above in the code for andrieuthomsh).

```
updateAMCMC.andrieuthomsh <- function(obj,...){
    mLoop <- get("mcmcloop",envir=parent.frame())
    if(iteration(mLoop)==(mLoop$burnin)+1){
        obj$restartit() # adaptation of h restarted after burnin
    }
    obj$incritno() # this line must appear below the above four lines obj$updateh()
    return(obj$returncurh())
}</pre>
```

 $^{^{1}}$ This just give h some extra freedom to explore the parameter space as compared to an algorithm that did not restart. Doing this does not affect the convergence of the algorithm
